Tropical Africa is affected by intense land use change, particularly forest conversion to agricultural land. In this study, the stream discharge of four small headwater catchments located within an area of 6 km² in western Kenya was examined for two years (2007, 2008). The four catchments cover a degradation gradient ranging from intact forest to agricultural land under maize cultivation for 5, 10 and 50 years. The runoff ratio (e.g. annual catchment discharge expressed as a percentage of rainfall) increased with increasing duration of cultivation from an average of 16.0% in the forest to 32.4% in the 50-year-old agricultural catchment. Similarly, the average runoff ratio due to the stormflow component was 0.033 in the forest and increased gradually to 0.095 with increasing duration of cultivation. The conversion from forest to agricultural land in the first 5 years caused about half of the total observed increases in runoff ratio (46.3%) and discharge in relation to rainfall (50.6%). The other half of the changes in discharge occurred later during soil degradation after forest clearing. With increasing duration of cultivation, soil bulk density (ρₚ) at a depth of 0-0.1 m increased by 46%, while soil organic carbon (SOC) concentrations and total porosity decreased by 75% and 20%, respectively. The changes in hydrological responses that occurred in the initial years after forest clearing may suggest a significant potential for improved land management in alleviating runoff and enhanced storm flow and moisture retention in agricultural watersheds.

KEY WORDS: cultivation; degradation gradient; forest conversion; headwater catchment; hydrology; runoff
Land use is one of the key parameters controlling fluxes in the hydrologic cycle. Removal of
forest cover typically results in a considerable increase in water yield (Bosch and Hewlett, 1982;
Farley et al., 2005) with significant effects on stream water quality, soil erosion and losses of
nutrients (Grip et al., 2004). The impact of land use change on hydrologic processes in the
tropics is particularly severe since soil degradation is more rapid than in temperate zones due to
more rapid mineralization of soil organic matter (SOM) and often high erosion where the
topography is steep and rainfall intensities are high (Spaans et al., 1989; Malmer and Grip, 1990;
Hartemink et al., 2008; Solomon et al., 2009). Changes in watershed dynamics in response to
deforestation in the humid tropics were widely investigated during the 1980s (Bruijnzeel, 1990;
Bonell and Balek, 1993) but less work has been done recently. Most of the earlier studies
focused on catchments in tropical Asia or Central and South America. Limited results from West
Africa show that forest clearing and subsequent land use significantly affect the magnitude of
runoff and erosion using plot studies (Lal, 1981). Yet there are few studies on stream water
discharge, runoff partitioning and their relation to land use change, particularly for East Africa
where forest pressures continue to be acute due to a rural population density which is among the
highest in the world (Kenya Forest Service, 2007).

Forest removal is a major factor increasing total stream water discharge and the proportion of
discharge occurring as storm runoff (Mumeka, 1986). In humid regions, the forest vegetation
transpires water throughout the entire year (Calder, 1998), whereas in agricultural landscapes
annual crops consume water only during the growing season. In addition, the larger plant litter
input and root turnover in forests compared to cropped fields maintain greater soil organic
carbon (SOC) concentrations, which in turn preserves soil structure and promotes higher infiltration capacities, lower Hortonian overland flow and greater water storage capacity (Fritsch, 1993). With continued cultivation over a period of years, particularly in low-input and subsistence systems, soils begin to lose SOC and become compacted, which has profound effects on soil hydrology (Giertz and Diekkruger, 2003; Awiti et al., 2008). Particularly in the tropics, SOC losses can be rapid (Solomon et al., 2007). It is, therefore, especially likely that for tropical agricultural landscapes, soil degradation, in addition to the loss of forest cover, has important impacts on stream water discharge.

The aim of this study was to quantify the effects of forest conversion to continuous cultivation on the stream discharge of headwater catchments in tropical Africa. The effects of cultivation on water yield were investigated for a chronosequence of four catchments in Western Kenya comprised of a forested headwater catchment and three headwater catchments under continuous maize production for 5, 10, and 50 years following forest conversion.

METHODS

The study site

The field measurements were done in Kapchorwa, located in the Nandi district in western Kenya (Fig. 1). The site is located 60 km northeast of Lake Victoria at longitude 35°0'0" E and latitude 0°10'0"N. The region belongs to the sub-humid ecological zone characterized by a bimodal rainy season with a mean annual precipitation of 2000 mm (Haupt, 2000). The “long rain season” is from April to June (~1200 mm) and the “short rain season” from August to October (~800 mm).
The site has an elevation of 1750-1900 m above sea level, an average maximum daily temperature of 26°C and an average minimum of 11°C (Glenday, 2006).

The Kakamega-Nandi forest in Western Kenya is the country’s only remaining tropical rain forest. Total forest cover in Kenya decreased by 0.3% year\(^{-1}\) on average between 1990 and 2005, to 35,220 km\(^2\), which represents 6% of the country’s territory according to the Global Forest Resources Assessment (FAO [Food and Agriculture Organization of the United Nations], 2006). The forest forms the easternmost relic of the Guinean-Congolian rainforest belt, which once spanned from East to West Africa. The area around this forest is among the most densely populated rural areas in the world. It had a population density of 578 persons per km\(^2\) in 1999 (Muller and Mburu, 2009), compared to 54 persons per square kilometer for the entire country (World Bank, 2008). Consequently the forest is under high anthropogenic pressure, which is mirrored by the decreasing natural forest cover and intensive cultivation (deGraffenried and Shepherd, 2009; Swallow et al., 2009). Past deforestation rates in the Kakamega-Nandi forest indicated a decrease of forest area and an increase in the fragmentation of natural, old-growth forest (Mitchell, 2004; Lung and Schaab, 2006).

Soils in the Kapchorwa catchment are kaolinitic Acrisols (FAO-UNESCO-ISRIC, 1988), which are classified as Ultisols in the US soil taxonomy (Soil Survey Staff, 1998). The parent material of these soils is principally granitic, with some inclusions of Precambrian gneisses, which supports Luvisols (Werner et al., 2007) and other undifferentiated basement system rocks at higher elevations (Jätzold and Schmidt, 1983). Soils in the study area have 45-49% clay, 15-25% silt, and 26-40% sand (Kimetu et al., 2008).
The forest section of the Kapchorwa catchment is part of the Kakamega-Nandi forest composed of tropical rainforest species. It is largely an indigenous forest with a 30-m closed canopy dominated by evergreen hardwood species. The most common species are *Funtumia africana*, *Ficus* species, *Croton* species, and *Celtis* species (Glenday, 2006). Other species include *Aningeria altissima* (A. Chev.), *Milicia excelsa* (Welw.) C.C. Berg, *Antiaris toxicaria* (Lesch) and *Chrysophyllum albidum* (G. Don), *Olea capensis* (L.) and *Croton megalocarpus* (Hutch) (Kinyangi, 2008). The above and below ground net primary production of trees in a tropical forest is estimated at 15.2 Mg ha\(^{-1}\) year\(^{-1}\) (Hertel et al., 2009). The agricultural catchments have maize as the main crop with farm sizes of less than 1 ha, and have been under maize cultivation since conversion from forest cover. Minor areas around the homesteads may include banana, coffee, and kitchen gardens. The soil is in most cases prepared by hand-held hoes and only in some cases ox plows. The maize grain yield without fertilizer input in the 5, 10 and 50 year old agricultural catchments are 6.5, 5.5 and 2.5 Mg ha\(^{-1}\) year\(^{-1}\), respectively (Ngoze et al., 2008).

**Hydrologic instrumentation and field data collection**

The headwater catchments were initially characterized in August 2006. The specific age classes designating when native forests were converted to agriculture were determined from historical community settlement patterns over the last century (Bleher et al., 2006). Specific years of conversion were verified from records of the Kenyan government from the Department of Forests, the Ministry of Agriculture, as well as from interviews with officials of local institutions and from county council records. Within each site, there were distinct population settlement patterns where newly acquired fields were excised from sections of the native forest for agriculture. All four headwater catchments are located within an area of 6 km\(^2\) and represent a
soil degradation gradient that corresponds to years under maize cultivation that has been used and its validity verified by several other studies (Solomon et al., 2007; Kimetu et al., 2008, 2009; Ngoze et al., 2008). Such chronosequences substitute time for space and have to be carefully selected to assure similar properties before the change (Huggett, 1998). Also hydrological differences between catchments unrelated to land cover have to be considered (Elsenbeer, 2001; Johnson et al., 2006). Therefore, the relationship between hydrological responses and physical watershed attributes such as size and slope as well as location characteristics such as rainfall were investigated as a source of random variation. Due to lack of replication, comparisons between individual watersheds should be viewed with caution and rather global trends across all four watersheds be interpreted.

Hydrologic instrumentation was installed in mid-December 2006 and catchments monitored for two years. The boundaries of each catchment were surveyed and delineated using a Global Positioning System (GPS). The GPS data were then used to generate a Geographical Information System (GIS) output and map of the area. The sizes of the catchments were 12.8 ha for the forest, 14.4 ha for the 5 year old conversion, 9.1 ha for the 10 year conversion and 10.0 ha for the 50 year conversion. A standard V-notch weir was constructed at each catchment outlet for determining stream discharge. The v-notch weirs had an angle of 60°, with an overall opening of 0.22 m² and a capacity of greater than 200 L min⁻¹ for a sharp-crested weir. They were located at a distance of 10 to 20 m from the spring. No overflow events were recorded. Stream stage was recorded using water level capacitance probes (Odyssey Dataflow Systems Pty Ltd, New Zealand) installed at the weir. The probes were programmed to give a reading of the average stream stage between 2-4 minutes. Data from these probes were downloaded biweekly. The weir
ratings were determined at low and intermediate flows using a stage downstream and discharge at the weir. The correlation coefficients of the weir ratings were $r^2 = 0.944$ ($y = 0.5483x - 12.079$), $r^2 = 0.915$ ($y = 0.5495x - 18.286$), $r^2 = 0.926$ ($y = 0.5329x - 16.382$), and $r^2 = 0.931$ ($y = 0.8608x - 48.769$) for the forest, 5 year, 10 year and 50 year conversions, respectively. Failure in data acquisition occurred occasionally and missing values were linearly interpolated using the stage downstream and weir rating equations.

Precipitation was determined from a tipping bucket rain gauge connected to a data logger installed 1 m above the ground surface in the agricultural catchments, representing open-area rainfall (e.g. rain gauges installed above the maximum canopy height). For all calculations, an average of open-area precipitation was used (CV of less than 1% between watersheds), but individual rain gauges are shown in Fig. 2 (average for the forest).

Five soil samples from 0-0.1 m depth were collected randomly by stratifying for location within slope and plateau of each catchment, after carefully removing the litter layer (capturing only the mineral horizon). The average slopes for the headwater catchments were measured using clinometers. The final average slope figure is a mean of five readings taken from the position of the weir up the slope. The resulting mean slope for the catchments were 7.5% for the forest, 6.4% for the 5-year conversion, 4.4% for the 10-year conversion and 5.8% for the 50-year conversion. Bulk density was determined from undisturbed soil cores; we used five soil samples from a depth of 0-0.1 m in each catchment (Campbell and Henshall, 1991). The soil porosity ($\phi$) was computed from bulk density ($\rho_b$) and particle density ($\rho_p$) using the formula $\phi = 1 - (\rho_b / \rho_p)$. 
Hydrological analysis

The stream hydrographs were normalized by corresponding catchment sizes to allow comparisons across the four catchments. The runoff ratio (RR) was computed for each catchment as the ratio of the total annual runoff to total rainfall (e.g., Berger and Entekhabi, 2001). Streamflow data were further analyzed using hydrograph separation implemented in WHAT (Web GIS based Hydrograph Analysis Tool) using the Recursive Digital Filter method for baseflow separation (Lim et al., 2005, 2010). This approach to hydrograph separation has been used in hydrological studies of forested and agricultural watersheds in tropical and temperate regions (Longobardi and Villani, 2008; Schwartz, 2007). Two other separation techniques, specifically the WHAT Local Minimum Method and the WHAT One Parameter Digital Filter Method (Lim et al., 2005) were used for comparison. The trends in the amount of baseflow and runoff were similar for all the methods, with a variation of up to 12.8% in the final results. Hydrologic parameters determined from the hydrograph separation include the baseflow and stormflow components of the runoff ratio ($RR_{BF}$ and $RR_{SF}$ as the ratio of total baseflow and stormflow to total rainfall, respectively). We also evaluated the baseflow index (BFI) as the ratio of baseflow to total discharge (Bloomfield et al., 2009). Cumulative flow duration curves (on a probability axis) were calculated to compare the differences in high, low, and median flows across the watersheds (Vogel and Fennessey, 1994). The flashiness of the water sheds was compared using the flashiness index method of Baker et al. (2004).

Laboratory measurements of soil properties and statistical analysis

Total C was determined by dry combustion after fine grinding soil using a Mixer Mill (MM301, Retsch, Germany). The five replicate samples were analyzed for total C with a Europa ANCA-GSL CN analyzer (PDZ Europa Ltd., Sandbach, UK) and considered as SOC since no carbonates are expected at pH values at and below 6 as found at these sites (Kimetu et al., 2008). SOM was determined by loss on ignition (Storer, 1984). The soil moisture retention curve was determined by applying soil suction to undisturbed soil cores (Klute, 1986).

Statistical analyses were done using JMP Version 8 (SAS Institute Inc, Cary, NC, USA) for soil properties and hydrological parameters for the four catchments. The comparisons were considered statistically significant at P<0.05 unless otherwise stated. A linear function was fitted for all the correlations.

RESULTS

The SOC concentrations in the topsoil (to 0.1 m) of the watersheds ranged from 28 to 108 mg g\(^{-1}\) and bulk densities from 1.2 to 0.8 g cm\(^{-3}\) depending on the conversion age (Table I). Porosity decreased from 0.70 to 0.56 and field capacity (at 0.33 bar) from 35 to 23% during land use conversion and long-term cultivation. There was no clear separation between the long rainy (April - June) and short rainy (August – October) seasons in the Kapchorwa catchment area during the study period (Fig. 2). Truly dry seasons occurred between November and March.

The streamflow response to precipitation events varied with land use history (Fig. 2). Unlike the flashy streamflow responses for catchments under cultivation, the discharge in the forest did not respond immediately to the rainfall. There was minimal storm runoff for the forest and a gradual
increase in the streamflow discharge in the forest during the rainy season that reached its peak in
October. The initial rainfall in April 2007 and 2008 following the usual dry season did not lead
to sudden increased discharge in agricultural catchments. After about one month of rainfall, the
streamflow exhibited periods of slowly increased discharge in the agricultural catchments
associated with rainfall.

The annual water yield of the catchments (expressed as specific discharge and as RR; Table II)
indicates a pronounced increase between forest and 5 years of cultivation, followed by a gradual
increase in the streamwater discharge with longer periods of cultivation. The RR for 2007 (e.g.,
total streamwater yield in relation to the precipitation) was 17.9% in the forest, 26.6% in the 5
year, 30.3% in the 10 year and 34% in the 50 year conversion to agriculture. The annual RR for
2008 in relation to the precipitation was 14.1% in the forest, 22.0% in the 5 year, 27.4% in the 10
year and 30.7% in the 50 year conversions. About half of the change (50.6%) in discharge as a
fraction of rainfall occurred over the first 5 years of cultivation after forest clearing, with the
remaining increase over the chronosequence (49.4%) observed for 5 to 50 years of cultivation.
This was consistent across the \( \text{RR}_\text{SF}, \text{RR}_\text{BF} \) and BFI hydrologic parameters (Table II). The
stormflow component of the runoff ratio (\( \text{RR}_\text{SF} \)) for the forested catchment increased from 0.033
and 0.029 to 0.092 and 0.097 after 50 years of cultivation (2007 and 2008 data, respectively).
Slightly less than half of the change (46.3%) was observed within the first 5 years of cultivation
(0.064 and 0.059 for 2007 and 2008, respectively). On average for both years, BFI decreased by
11% over 50 years of continuous agriculture following forest clearing. Slightly less than half
(45%) of that decrease occurred after forest clearing and within the first 5 years of cultivation.
On average for both years, the flashiness index after forest conversion was 30 times higher after
5 years of cultivation, and 45 times higher after 50 years of cultivation (Table II). The flow duration analysis followed the pattern of the runoff ratio (Fig. 3). The 10-year curve evolves towards the 50-year curve for high frequency flows and matches the 5-year curve for low frequency flows (i.e., high flows).

Streamwater discharge as a percentage of rainfall and the runoff ratio were inversely related to SOC (P<0.01) and total porosity (P<0.05) and positively correlated to $\rho_b$ (P<0.05; Table III). Conversely, BFI had a significant inverse relationship with $\rho_b$ (P<0.05), positive correlation with total porosity (P<0.05), but was not significantly correlated with SOC. There were no significant relationships between the three aforementioned hydrological properties and either the average slope or catchment size (P>0.05) that would indicate a bias in watershed responses due to random spatial effects.

DISCUSSION

Changes in soil properties

The changes in SOC and soil physical properties were in agreement with previous studies on over 100 farm fields in the same region (Kimetu et al., 2008; Kinyangi, 2008) of which these watersheds represent a subset. Measured porosity and field capacity correspond to changes in available water capacity noted by Moebius-Clune et al. (2011) for 36 farms in the same region. Therefore, these watersheds are broadly representative of the studied region and corroborate
more rigorously replicated studies. Qualitatively, the changes in soil hydraulic properties agree
with a study by Price et al. (2010) in the USA who found as much as 38% higher bulk densities
and seven times lower saturated hydraulic conductivity in lawn and pasture soils compared to
forest soils.

Effects of forest removal

The conversion of forest to maize cultivation led to drastic changes of the vegetation cover that
significantly affected the stream discharge and flashiness. The runoff ratio (RR, discharge
expressed as a percentage of the rainfall) increased by an average of 44.2% while flashiness
increased thirty fold from forest to the adjacent catchment after 5 years of maize cultivation
(Table II). This translates to an average increase of stream discharge by 34.4 mm year\(^{-1}\) (8.8%),
and six fold increase in flashiness per year. Similar stream discharge values were reported from
other conversion studies. Low and Goh (1972), reporting on catchment research in peninsular
Malaysia, showed an annual increase of 10% in water yield in a largely cleared catchment
compared to yield trends in three forested catchments. A study by Ruprecht and Schofield (1989)
in a catchment area of 94 ha showed that clearing native vegetation and establishment of
agricultural plants on a small catchment in southwest Australia resulted in a large streamflow
increase. The RR increased by 10% in the first year after clearing and continued to increase
linearly at a slower rate of 3% per year for a further six years, when a new streamflow
equilibrium was reached (Ruprecht and Schofield, 1989).
The reduced water use of annual crops such as maize compared to a full-grown forest reflects not only the diminished capacity of short vegetation to intercept and evaporate rainfall (Van Dijk and Bruijnzeel, 2001), but also its ability to extract water from deeper soil layers during periods of drought (Eeles, 1979). The former relates primarily to the lower aerodynamic roughness of short annual crops (and possibly to their lower leaf area index), whereas the reduced water uptake of crops reflects their more limited rooting depth (Nepstad et al., 1994; Calder, 1998). In the forest, rainfall reaching the soil (throughfall) may be reduced by interception to a greater extent than in maize fields. In the Cerrado region of Brazil, Lilienfein and Wilcke (2004) reported interception losses of 11-24% in maize fields and 16-26% in a pine plantation, but only less than 11% in native Cerrado vegetation. However, variability of throughfall and stemflow to estimate interception may be highly variable in space and time as seen for a palm-rich forest in Amazonia (Germer et al., 2006).

Unlike the forested catchment, the immediacy of streamflow response to rainfall as seen from the higher flashiness for the catchment under 5 years of continuous cultivation (Fig. 2) suggests that part of the rainfall follows a rapid route to the stream channel, producing quickflow. In the forest, the combination of permanent soil cover, litter layer and roots acts as a sponge soaking up water during rainy spells and releasing it more evenly than in annual cropping systems (Bruijnzeel, 2004a), which corroborates our results (Fig. 2A). The beneficial effects of higher organic matter contents and abundant faunal activity in forests on soil aggregate stability and water intake capacity may be retained for a year or two after clearing (Bruijnzeel, 2004b). However, soil and aggregate disturbance through cultivation together with reduced litter input generally leads to a rapid decline thereafter (Lal, 1987). Lal (1983) studied a 44-ha forested
drainage basin on an Alfisol in the humid tropical area of western Nigeria from 1979 to 1981. He observed virtually no Hortonian overland flow and soil erosion and attributed it to the thick undergrowth and leaf litter layer. Deforestation significantly increased the total water yield by 140 mm per year (10%) from 1979 to 1981 (Lal, 1983).

An additional aspect in agricultural catchments is that considerable areas may become permanently occupied by compacted surfaces such as houses, yards, trails and paths. This is almost inevitably followed by increases in amounts of runoff (Grip et al., 2004). In contrast to our study, Giertz et al. (2005) showed in sub-humid, tropical Benin that continuous cropping for 100 years led to a streamwater discharge yield of 16.4% (190 mm) of the rainfall per year, which was only a small increase compared to a yield of 10.2% (117 mm) in the forest catchment. However, in the Benin study, both the forest and agricultural catchments were larger in size than in our experiment; about 300 ha each. Rigorous experimental designs like the ‘paired catchment’ technique have produced detectable changes in streamflow also including large basins (Trimble et al., 1987; Bruijnzeel, 1990; Malmer, 1992; Fritsch, 1993; Costa et al., 2003). In all cases, the removal of more than 33% of forest cover resulted in significant increases in annual streamflow during the first 3 years. Initial gains in water yield after complete forest clearance ranged between 145 mm year$^{-1}$ (9.7%) and 820 mm year$^{-1}$ (32.8%) (Bruijnzeel, 1990; Malmer, 1992; Fritsch, 1993). In addition, increases in water yield proved to be roughly proportional to the fraction of biomass removed. These changes in water yield mainly reflect the different evaporative characteristics of mature tropical forest and (very) young secondary or planted vegetation and, to a much lesser extent, increases in storm runoff (response to rainfall). Under mature tropical rain forest, typically 80–95% of incident rainfall infiltrates into the soil, of which
over 1000 mm year\(^{-1}\) (67\%) is transpired again by the trees when soil moisture is not limiting, whereas the remainder sustains streamflow (Bruijnzeel, 2004a). Chevallier and Planchon (1993) found a mean annual evapotranspiration of 1600 mm in a 4-year study in a 136 ha humid savannah basin in Ivory Coast.

During the dry seasons, the water discharge in the studied agricultural watersheds gradually diminished to low levels but never dried completely due to the relatively short dry season compared to the duration of the groundwater-derived baseflow recession (Fig 2). A review by Bruijnzeel (2004b) suggests that the water holding capacity i.e., ‘sponge effect’ is lost after clearing, resulting in diminished dry season flows. The 42.6\% increase in RR from the forest to the maize fields after 5 years of cultivation is consistent with the study by Giertz et al. (2005) in Benin. In the Benin study, RRs were 0.095 and 0.158 for the forest and agricultural catchments, respectively. In formerly forested areas in Indonesia, typical surface RR associated with bench terraced rainfed agriculture on volcanic soils in upland West Java also ranged from 0.16 to 0.18 for terraces on moderately steep slopes to greater values of 0.27 – 0.33 on steep slopes (Purwanto and Bruijnzeel, 1998). Our data and data from various other studies therefore indicate that conversion to agriculture causes immediate shifts in the hydrological behavior of headwater catchments.

**Effects of cultivation**

We found the overall increase in RR and storm discharge between forested and the catchment cultivated for 5 years to be similar to the increase in RR and RR\(_{SF}\) between the catchment cultivated for 5 years and the catchment cultivated for 50 years (Table 2), which may be
explained by the continued and significant changes in soil properties that accompany continued
cultivation. Despite the greater increase in runoff ratio per year between forest and 5 years of
cultivation (15% year\(^{-1}\)) compared to the following 45 years (1% year\(^{-1}\)), the total change after
forest clearing and during the first 5 years (43% of total increase) or between 5 and 50 years
(57% of total increase) after forest conversion suggests long-term soil changes and their
management to be important drivers of headwater hydrology in addition to changes in vegetation
cover. The increase in flashiness by an average of 61% from the 5 and 10 year old conversions
also supports this argument. The 10-year flow duration curves (Fig. 3) evolve towards the values
of the 50-year curve during the most common flows suggesting that baseflow is still the most
dominant regime in the landscape. For the rare high flows, the 10-year conversion matches the 5-
year conversion suggesting the possibility of compaction following cultivation.

The increase in topsoil \(\rho_b\) from the 5- to the 50-year old agricultural catchment (similar to
findings from a much larger set of 53 farms at the same site by Kinyangi, 2008) may be an
indication of changes in the soil profile that cause reduced rainfall infiltration. Similarly,
Moebius-Clune et al. (2011) observed a loss of water-stable aggregates of over 90% to less than
40% on 36 farms in the same chronosequence. Several factors may contribute to loss of
aggregation and reduced infiltration including continued exposure of bare soil after forest
clearance to intense, high energy rainfall (Lal, 1996), loss of SOC (Table I; Solomon et al.,
2007), compaction of topsoil by mechanical operations (Malmer and Grip, 1990) or grazing
(Gilmour et al., 1987), gradual disappearance of soil faunal activity (Aina, 1984), and increases
in the area occupied by impervious surfaces such as paths and settlements (Ziegler and
Giambelluca, 1997). Increased bulk density and reduced infiltration may lead to a more
pronounced catchment response to rainfall (Giertz and Diekkruger, 2003) and increases in storm runoff during the rainy season may become so large as to seriously impair the recharging of the soil and groundwater reserves feedings springs and maintaining baseflow.

It is not clear, however, whether lower infiltration at the soil surface triggered the observed greater runoff, since infiltration rates may still be greater than rainfall intensities (Zimmermann et al., 2006). Often, subsurface compaction (e.g. a plow-pan) may rather be responsible for overland flow through saturation excess in the surface layer. A perched water table was found to be responsible for a doubling in runoff events and a 17-fold increase in runoff volume by conversion of forest to pasture in western Amazonia (Germer et al., 2010). We are not able to distinguish between subsurface and soil surface processes that led to the observed increases in runoff in our study. It is unlikely, however, that a subsurface layer with low permeability is present in all watersheds which caused the greater proportion of runoff through a perched water table, as we would not expect greater runoff with longer duration of maize cultivation without other changes in management or plant cover. However, compaction of not only the topsoil but also the subsoil through cultivation may be a possible explanation for the observed greater runoff.

In the Benin study, Giertz et al. (2005) attributed the reduction of soil permeability after 100 or more years of cultivation to lower abundance and activity of soil organisms due to the mechanical destruction of the soil structure as well as a decrease in litterfall (Edwards and Bohlen, 1996). Lower microbial activity (Kimetu et al., 2009) was also found at our sites but an
explicit connection between microbial activity and soil hydrological properties has not been examined. Pedobiological investigations by Giertz et al. (2005) also demonstrated that a reduction of macrofauna activity on agricultural fields compared with natural vegetation may cause an extreme reduction of macropores at the soil surface. Reduced macroporosity is an important contributor to lower permeability of the surface in agricultural catchments. An explicit connection between macrofauna and soil permeability was not examined in our study, but could well have played a role in increasing the runoff ratio.

Following 50 years of cultivation in the Kapchorwa catchments, the ability of the topsoil (0-0.1 m) to hold moisture at field capacity was reduced by about 34% (Table 1), similar to changes in available water capacity found by Moebius-Clune et al. (2011) for a larger set of sites in the same area. This may be attributed to losses in SOC, erosion of finer soil particles, or mechanical compaction. Soil organic C losses have been found to be significant with 67-86% over 100 years following forest conversion to permanent cultivation at our study site (Solomon et al., 2007). Similar results are obtained using SOC stocks with fixed sampling depth (Nguyen et al., 2008) or with equivalent mass (Kinyangi, 2008). Such SOC losses can only be compensated with organic matter amendments (Kimetu et al., 2008). Therefore, maintenance of SOC and soil biological activity, including soil macrofauna, may help reduce storm runoff and, to some extent, stream discharge in tropical headwater catchments to compensate for the loss of maintenance of a forest cover. Whether such interventions in the topsoil would actually reduce discharge cannot be proven and warrants manipulative experimentation, especially if key changes occurred in the subsoil that triggered increases in runoff. In addition, maintenance of some forest cover could
significantly improve flow regime as seen in a range of mixed land use watersheds in North Carolina (Price et al., 2011).

CONCLUSIONS

The increase of surface runoff as a result of the loss of forest cover was similar in magnitude as increases observed corresponding to long-term cultivation. This would suggest that preservation of forest cover is only one avenue for decreasing storm water runoff and discharge from headwaters. Equally important may be the maintenance of infiltration and water retention in soil, but it is not clear to what extent subsurface changes contributed to the observed runoff responses. Further experimentation is required to evaluate whether discharge and runoff can be reduced by SOC build-up, reduced compaction of surfaces or plough pans or less sealing of surfaces. This would have important implications for policy interventions to promote soil conservation techniques such as no-tillage, mulching, crop rotations or intercropping. Questions arise whether nutrient and SOC losses follow the same trends as water discharge shown here. In addition, soil management that maintains water retention and decreases runoff and discharge warrant evaluation on a watershed scale.

ACKNOWLEDGEMENTS

The authors would like to thank Brett Gleitsmann for assistance in identifying the study sites, constructing the weirs and doing initial sampling. We thank Henry Biwott for help with field work. This research was financially supported in part by grants from the Ford Foundation International Fellowships Program, the National Science Foundation Grant No. 0215890 through
CIIFAD, the Biogeochemistry and Environmental Biocomplexity Small Grant Program Ref. DGE 0221658, Towards Sustainability Fund, the Institute for African Development and the Norman Borlaug Leadership Enhancement in Agriculture Program Fellowship. Logistical support was provided by the World Agroforestry Centre Kisumu office. We thank the anonymous referees for their valuable suggestions.
